Abstract. We study the local environment properties of a sample of 26 gamma-ray bursts with early optical detection, among which 8 show possible reverse shock emission. We are particularly interested in intrinsic X-ray column density along the line of sight ($N_H(z)$) and optical extinction in V band (A_V). We compare our sample with larger and more general samples and check if presence of the reverse shock emission is somehow related to the surrounding environment.

Key words. gamma-rays: bursts – X–rays: general – dust extinction

1. Introduction

Based on the standard fireball model of gamma-ray bursts (GRBs), optical afterglow is produced when relativistic shell collides with the external medium and decelerates. In this simple scenario, optical light curve of a typical afterglow should be composed of different power-law segments that show shallow rise or decay. We can model the light curve with $F = t^{\alpha}$, where F is flux density and α is power-law index, with typical forward shock indices being $\alpha_{\rm rise} \lesssim 1/2$ and $\alpha_{\rm decay} \sim -1$ (Sari, Piran & Narayan 1998). However, at early times, optical light curve can show flares with steep rising and decaying. One mechanism for such behaviour can be the reverse external shock (Sari & Piran 1999), which propagates back into the relativistic shell and decelerates it, producing bright optical flash in the light curve (Kobayashi 2000), with indices $\alpha_{\rm rise} \sim 5$ and $\alpha_{\rm decay} \sim -2$ (Zhang, Kobayashi & Mészáros 2003). In this case, central engines could be magnetized (Zhang, Kobayashi & Mészáros 2003), although the magnetization should not be too large, otherwise it can also suppress the reverse shock emission (Zhang & Kobayashi 2005; Fan, Wei & Wang 2004).

The paucity of observed reverse shock (RS) emission (Gomboc et al. 2009) could be either related to the central engine processes (for example, magnetization), or perhaps to the GRBs' surrounding environment. To examine this possibility, we build a sample of 26 GRBs with early optical detection, among which 8 show possible reverse shock emission. We concentrate on GRBs with known redshifts, observed with *Swift* XRT, to determine the value (or upper limit) of intrinsic X-ray column density. We collect data from the

literature, i.e., from Campana et al. (2010) and Evans et al. (2009) for $N_H(z)$, while for A_V we use Kann et al. (2010). Data for our sample are presented in Table 1, together with references from which we obtain the information about possible RS emission.

The sample excludes GRBs 990123, 021004, 021211, 041219A, 060111B and 060117, which show possible RS emission, and 050502A, which shows no RS emission. These GRBs were detected in optical at early times after the GRB trigger, but they were excluded from our analysis because either no redshift is known or no $N_H(z)$ could be obtained.

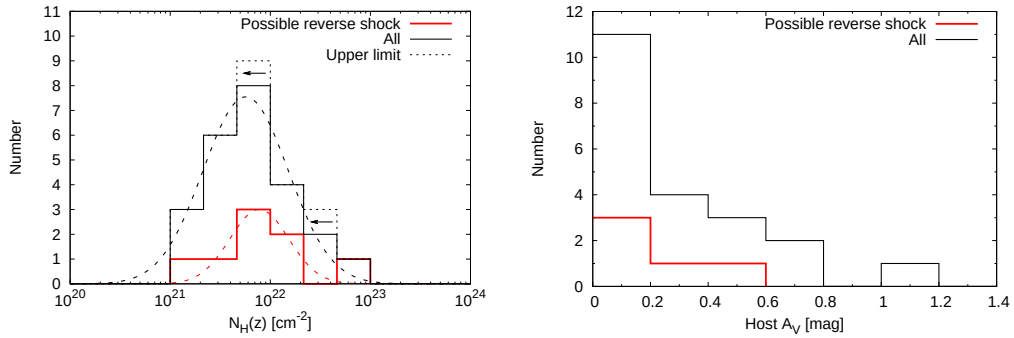

Fig. 1. Left: $N_H(z)$ distribution for our sample. Red color indicates GRBs with possible RS emission, while black color indicates all GRBs from our sample. Also added separately are two upper limits. Red and black dashed lines represent the fitted Gaussian functions in log space, for which the parameters are discussed in the text. Right: A_V distribution for our sample. Red color indicates GRBs with possible RS emission, while black color indicates all GRBs from our sample.

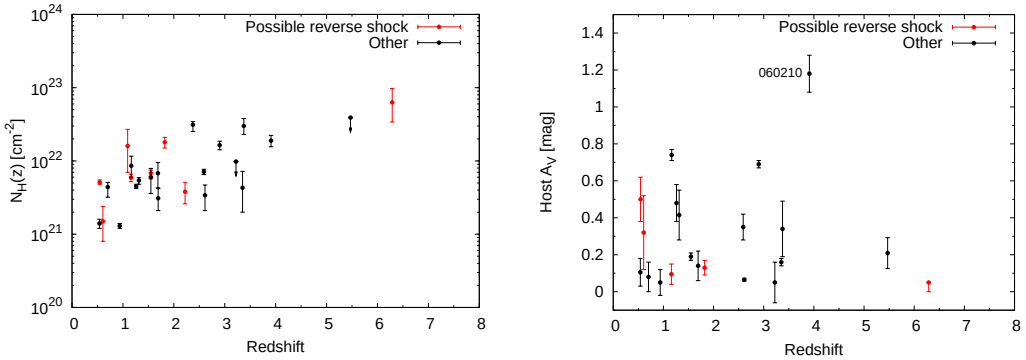

Fig. 2. Left: $N_H(z)$ versus redshift for our sample. Right: A_V versus redshift for our sample. Red points indicate GRBs with possible RS emission, while black points indicate all other GRBs from our sample. In the right plot we marked GRB 060210, which has the highest A_V, but this value might have been overestimated.

2. Analysis and Discussion

Results are presented in Figure 1, which shows the distributions of $N_H(z)$ and A_V for our sample, and in Figure 2, which shows $N_H(z)$ and A_V versus redshift. We find that our results are comparable to results for larger samples, i.e., Figure 1 and Figure 2 from Campana et al. (2010) and to Figure 2 and Figure 3 from Kann et al. (2010). We fitted the $N_H(z)$ distribution with a Gaussian function in log space, excluding two upper limits. We get mean $\log N_H(z) = 21.8$ and standard deviation $\sigma_{\log N_H(z)} = 0.4$ (reduced χ^2 of the fit is 0.5 with 3 d.o.f.) for all GRBs from our sample, while for GRBs that show possible RS emission we get mean $\log N_H(z) = 21.9$ and standard deviation $\sigma_{\log N_H(z)} = 0.3$ (reduced χ^2 of the fit is 0.6 with 3 d.o.f.). These results are comparable to the value of log-normal distribution fit from Campana et al. (2010), with the mean $\log N_H(z) = 21.9$ and standard deviation $\sigma_{\log N_H(z)} = 0.5$. Calculating the median value for A_V distribution, we find $A_V = 0.19 \pm 0.14$ mag, which is comparable to the mean value from Kann et al. (2010), who reported the value 0.21 mag for their Golden Sample.

The comparison of $N_H(z)$ and A_V for GRBs that show possible RS emission to other GRBs in our sample shows that they tend to have sim-

ilar distributions (Figure 1). The subsample of GRBs with possible RS emission covers a large redshift interval, from $z = 0.54$ to $z = 6.29$. A slight trend of higher $N_H(z)$ at higher z can be seen in the left plot in Figure 2, as already mentioned by Campana et al. (2010) on larger and more general sample. This can also be seen for GRBs without possible RS emission from our sample (excluding the upper limit at $z = 5.47$), although in this case $N_H(z)$ values are a bit more scattered, but they span in redshift only up to $z = 3.91$.

From the right plot in Figure 2 we see that GRBs with possible RS emission tend to have lower A_V at higher redshifts, but this can be due to selection bias and small sample size. Anyway, the same trend is not so evident for other GRBs in our sample, which seem to be more scattered in A_V versus redshift plot. Note the GRB 060210, which has the highest A_V among GRBs in our sample, but as already mentioned by Kann et al. (2010), this extinction might have been overestimated. Kann et al. (2010) noticed on a larger sample that GRBs at higher redshifts tend to have lower A_V on average, but they concluded that it is unclear whether this is due to selection effects or due to the evolution of dust properties.

3. Conclusion

Using a sample of GRBs with early optical detections, among which some show possible reverse shock emission, we compare intrinsic X-ray absorption ($N_H(z)$) and host galaxy optical extinction (A_V) between GRBs from our sample and GRBs from more general samples, presented in Campana et al. (2010) and Kann et al. (2010). We find no evident discrepancies of host galaxy properties between these samples. This seems to indicate that there are no host galaxy environment differences, and also that the effectiveness of the reverse shock emission is most probably more linked to the central engine processes than to the progenitor's surrounding.
