**Abstract.** The discovery of deep spectral features in the X-ray spectrum of 1E1207.4-5209 focussed the attention of the astronomical community on this radio-quiet NS, making it the most intensively observed INS ever. The harvest of X-ray photons, collected mainly by *XMM-Newton*, unveiled a number of unique characteristics, raising questions on this source very nature.

**Key words.** Pulsars: individual (1E 1207.4-5209) – Stars: neutron – X-ray: stars

### 1. Introduction

Neutron star atmosphere models predicted the presence of absorption features depending on atmospheric composition, but high quality spectra, collected both by *Chandra* and by *XMM-Newton*, did not yield evidence for any such feature (see Pavlov et al. 2002a and Becker & Aschenbach 2002 for recent reviews). INS spectra are well fitted by one or more black-body curves with, possibly, a power law contribution at higher energies, but with no absorption or emission features. The spectrum of 1E1207.4-5209, on the contrary, appeared from the start as dominated by two broad absorption features seen, at 0.7 and 1.4 keV, both by *Chandra* (Sanwal et al. 2002)

and *XMM-Newton* (Mereghetti et al. 2002). To better understand the nature of such features, *XMM-Newton* devoted two orbits to 1E1207.4-5209, for a total observing time of 257,303 sec. In the two MOS EPIC cameras the source yielded 74,600 and 76,700 photons in the energy range 0.2 - 3.5 keV, while the pn camera recorded 208,000 photons, time-tagged to allow for timing studies. Analysis of this long observation, while confirming the two phase-dependent absorption lines at 0.7 and 1.4 keV, unveiled a statistically significant third line at  $\sim 2.1$  keV, as well as a possible fourth feature at 2.8 keV. The nearly perfect 1:2:3:4 ratio of the line centroids, as well as the phase variation, naturally following the pulsar B-field rotation, strongly suggest that such lines are due to cyclotron resonance scattering (Bignami et al.

2003). A year after the *XMM-Newton* observation, 1E 1207.4–5209 was deeply scrutinized by *Chandra* for  $\sim 300$  ksec, thus logging an overall effective exposure slightly larger than that devoted to the most popular NSs so far, such as Crab, Vela and RX J1856.5–3754.

The release of a new, and improved, instrument calibration software prompted us to revisit the *XMM-Newton* data set. Here we shall briefly report on some highlights of our new spectral and temporal analysis (see De Luca et al. 2004 for details). In addition, the “best” X-ray positional information is used, in conjunction with a new optical observation, to investigate the source optical behaviour.

## 2. Timing Analysis

After converting the arrival times of the 208,000 pn photons to the Solar System Barycenter, we searched the period range from 424.12 to 424.14 ms using both a folding algorithm with 8 phase bins and the Rayleigh test. The best period value and its uncertainty ( $P = 424.13076 \pm 0.00002$  ms) were determined following the procedure outlined in Mereghetti et al. (2002). Comparing the new period measurement of 1E 1207.4–5209 with that obtained with *Chandra* in January 2000 (Pavlov et al. 2002b), we obtain a period derivative  $\dot{P} = (1.4 \pm 0.3) \times 10^{-14} \text{ s s}^{-1}$ . However, Fig. 1 (left panel) shows that the  $\dot{P}$  value rests totally on the first *Chandra* period measurement. Using only the 3 most recent values, the period derivative is unconstrained. Thus, we cannot exclude that the observed spin-down, based on only a few sparse measurements, be affected by glitches or Doppler shifts induced by orbital motion. Questioning the object’s  $\dot{P}$  would have far reaching consequences for the understanding of 1E1207.4–5209 since the serious discrepancy between the pulsar characteristic age ( $\tau_c \sim 5 \times 10^5$  yrs) and the SNR age ( $\tau_{SNR} \sim 7$  kyrs) is entirely based on the value inferred from the measurements summarized in Fig. 1 (left panel).

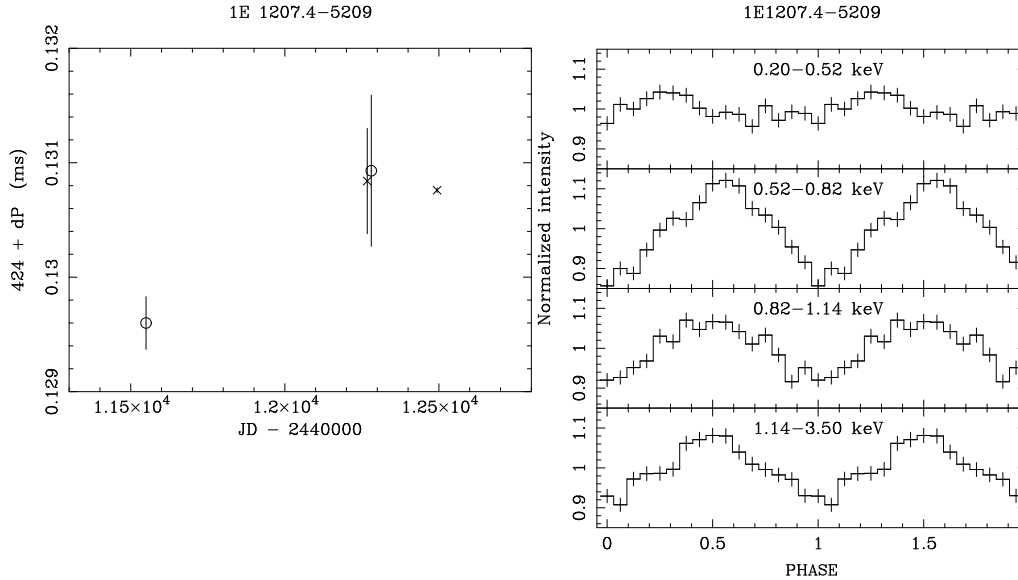

To study the energy dependence of the pulse profile, we divided the data in four channels with approximately 52,000 counts each: 0.2–0.52 keV, 0.52–0.82 keV, 0.82–1.14 keV

and 1.14–3.5 keV. The pulse profiles in the different energy ranges (Fig. 1, right panel) show a broad, nearly sinusoidal shape, with a pulsed fraction varying from  $\sim 3$  to  $\sim 11$  % in the four energy intervals. It is worth noting that the minimum pulsed fraction is found in the 0.20–0.52 keV energy range, the only portion of the spectrum free from absorption lines. Indeed, Fig. 1 (right panel) is an independent confirmation of the findings of Bignami et al. (2003) who ascribed the source pulsation to the absorption lines phase variation.

Finally, comparing the shapes of the light curves of Fig. 1 (right panel), we see for the first time a phase shift of nearly  $90^\circ$  between the profile in the lowest energy range ( $< 0.52$  keV) and those at higher energies.

## 3. Spectral analysis

The improved understanding of the instruments (concerning, e.g., its Quantum Efficiency, its Charge Transfer Inefficiency, and its redistribution function) implemented in the most recent SAS release used here (SAS v5.4.1) yields rather significant differences in the low energy ( $E < 0.6$  keV) part of the spectrum with respect to our previous analysis (Bignami et al. 2003). This allowed for an update of the best fitting parameters for both the continuum and the lines. The reader is referred to De Luca et al. (2004) for a complete discussion of the spectral analysis of the three EPIC cameras. Here we shall focus on the pn data set, which contributes more than half of the source statistics. The best fitting continuum model comes from the sum of two blackbody functions. The cooler one has a temperature  $kT = 0.163 \pm 0.003$  keV and an emitting radius  $R = 4.6 \pm 0.1$  km, while the hotter one has  $kT = 0.319 \pm 0.002$  and  $R = 0.83 \pm 0.03$  km. Four absorption features are clearly seen in the spectrum of 1E 1207.4–5209 (see Fig 2) at the harmonically spaced energies of  $\sim 0.7$  keV,  $\sim 1.4$  keV,  $\sim 2.1$  keV and  $\sim 2.8$  keV. The different spectral continuum model, resulting from the improved calibrations, yields also a more significant detection of the third and fourth features with respect to our previous analysis. Using a simple gaussian in absorption, we es-

**Fig. 1.** (Left) Period history of 1E 1207.4–5209. Circles are the *Chandra* measurements, crosses *XMM-Newton*. (Right) Folded light curve of 1E 1207.4–5209 in four energy ranges. Fitting the pulse profiles with a function consisting of a constant plus a sinusoid, we obtain pulsed fraction values of  $(2.7 \pm 0.7)\%$  in the 0.2–0.52 keV energy range,  $(11.1 \pm 0.7)\%$  for 0.52–0.82 keV,  $(7.1 \pm 0.7)\%$  for 0.82–1.14 keV, and  $(7.1 \pm 0.7)\%$  1.14–3.5 keV.

timated with an F-test that the 2.1 keV and the 2.8 keV features have a chance occurrence probability of  $\sim 10^{-9}$  and  $\sim 10^{-3}$ , respectively.

As a further step, we have studied the variations of the spectrum of 1E 1207.4–5209 as a function of the pulse phase. Following Bignami et al. (2003), we selected the phase intervals corresponding to the peak (phase interval 0.40–0.65 with respect to Fig. 1, right panel), the declining part (phase 0.65–0.90), the minimum (phase 0.90–1.15) and the rising part (phase 0.15–0.40) of the folded light curve. The resulting spectra (see Fig. 3) were fitted allowing both the thermal continuum and the lines to vary. The main results can be summarized as follows:

- The two components of the continuum vary slightly both in temperature and in flux with the pulse phase, accounting at most for  $\sim 3\text{--}5\%$  of the source pulsation. An inspection of Fig. 3 clearly shows that the phase variation of the features is largely re-

sponsible for the observed pulsation of the source.

- the features are strongly dependent on the pulse phase and show significant variations in width, depth and shape. The central energy of the 0.7 keV feature varies by 6% at most, while displacements of the other features are not significant. The 2.8 keV feature is only marginally detected during the minimum and the rise intervals.
- The relative intensity of the first three features varies with the phase.

#### 4. Optimizing the X-ray position

To derive the sky coordinates of 1E 1207.4–5209, we computed independently for the MOS1 and MOS2 cameras the boresight correction to be applied to the default EPIC astrometry. We used the Guide Star Catalog II (GSC-II<sup>1</sup>) to select, amongst our  $\sim 200$

<sup>1</sup> <http://www-gsss.stsci.edu/gsc/gsc2>

**Fig. 2.** The spectrum of 1E 1207.4-5209 as seen by the pn camera. The upper panel shows the data points together with the best fitting continuum model folded with the instrumental response. The lower panel shows the residuals in units of standard deviations from the best fitting continuum. The presence of four absorption features at  $\sim 0.7$ ,  $\sim 1.4$ ,  $\sim 2.1$ ,  $\sim 2.8$  keV is evident.

serendipitous detections, 6 sources with a stellar counterpart to be used to correct the EPIC astrometry. The rms error between the refined X-ray and GSC-II positions is  $\sim 1$  arcsec per coordinate. The resulting MOS1 position of 1E 1207.4-5209 is  $\alpha_{J2000} = 12h10m00.91s$ ,  $\delta_{J2000} = -52^{\circ}26'28.8''$  with an overall error radius of 1.5 arcsec. The MOS2 position is  $\alpha_{J2000} = 12h10m00.84s$ ,  $\delta_{J2000} = -52^{\circ}26'27.6''$ , also with an uncertainty of 1.5 arcsec, fully consistent with the MOS1 coordinates.

In order to obtain an independent measurement on the position of 1E 1207.4-5209, we have retrieved from the *Chandra* Data Archive a public dataset relative to a recent (June 2003) ACIS observation (20 ksec in imaging mode) of the target. As in the case of the EPIC data, we used the positions of the serendipitous sources in the field to refine the astrometry (see De Luca et al. 2004 for details). The best *Chandra* /ACIS position of 1E 1207.4-5209 is  $\alpha_{J2000} = 12h10m00.826s$ ,  $\delta_{J2000} =$

$-52^{\circ}26'28.43''$  with an uncertainty of  $0.6''$ . The more accurate *Chandra* position lies inside the intersection of the MOS1 and MOS2 error circles, confirming the correctness of the analysis and the absence of systematics.

## 5. Search for the optical counterpart

The field of 1E 1207-5209 was observed with the 8.2-meter UT-1 Telescope (Antu) of the ESO VLT (Paranal Observatory). Observations were performed with the the FOcal Reducer and Spectrograph 1 (FORs1) instrument. Images were acquired through the Bessel *V* and *R* filters for a total integration time of  $\sim 2$  and 3 hrs, respectively. Fig. 4 shows the inner portion of the combined FORs1 *V*-band image centered on the target position, with the ACIS, MOS1 and MOS2 error circles superimposed. A faint object (marked with the two ticks in Fig. 4) is detected just outside the southern edge of the MOS1 error circle. It showed variability during the time span covered by our ob-

**Fig. 3.** (Left) Comparison of the four phase-resolved spectra extracted from pn data. Colours indicate the phase-interval: black, minimum; red, rise; green, peak; blue, decline. The peak of the total light curve corresponds to the phase interval where the absorption features are at their minimum, while the light curve minimum happens when the absorption features are more important. (Right) Residuals in units of sigma obtained by comparing the data with the best fit continuum model for the phase-resolved spectra. The pulse phase variations in width, depth and shape of the absorption features are evident.

servations. Also, its position falls more than 2 arcsec away from the most probable region. For both reasons, we can rule it out as a potential counterpart of 1E 1207.4–5209.

No candidate counterpart is detected within the *Chandra* error circle (nor in the intersection of the MOS ones) down to  $R \sim 27.1$  and  $V \sim 27.3$ , which we assume as upper limits on the optical flux of 1E 1207–5209. For an X-ray derived interstellar absorption of  $A_V = 0.65$  at  $b \sim 10^\circ$  and a distance of 2 kpc, our VLT u.l. rules out any hypothetical “normal” stellar companion ( $M > 15$  both in R and in V). If we assume that 1E 1207-5209 is indeed *isolated*, we can derive a neutron star optical luminosity  $\leq 3.4 \cdot 10^{28} \text{ erg s}^{-1}$  or  $\leq 4.6 \cdot 10^{-6}$  of its rotational energy loss, a value similar to those of middle-aged INSS. Since the VLT flux upper limits are  $\geq 100$  higher than the extrapolation of the *XMM-Newton* blackbody (De Luca et al. 2004), they do not constrain our object’s optical spectrum.

## 6. Conclusions

1E 1207.4–5209 is a radio-quiet NS at the center of a well known SNR. However, the longer we observe such an object, the harder it becomes to make it fit into a known class of the NS family. The long observations devoted to 1E 1207.4–5209 both by *Chandra* and by *XMM-Newton* have unveiled a number of unique and somewhat contradictory characteristics that, at the moment, defy standard theoretical interpretations.

The first and outmost problem seems to be the interpretation of the period evolution. The usual, simplistic, monotonic fit yields a  $\dot{P} = (1.4 \pm 0.3) \times 10^{-14} \text{ s s}^{-1}$  that, combined with the period value, makes 1E 1207.4–5209 much too old ( $> 50$  times) for its SNR. Moreover, the value of the star’s magnetic field inferred on the basis of the classical dipole braking formula ( $B = 2.6 \pm 0.3 \times 10^{12} \text{ G}$ ) is significantly different from the value obtained from the cy-

**Fig. 4.** FORS1 V-band image centered on the target position. The error circles from *Chandra* /ACIS (0.6'' radius), MOS1 and MOS2 (2 arcsec radius) have been superimposed.

clotron absorption lines interpreted both in terms of electrons ( $B \sim 8 \times 10^{10}$  G) as well as protons ( $B \sim 1.6 \times 10^{14}$  G).

More creative interpretations of the period evolution (e.g. De Luca et al. 2004; Zavlin

et al. 2004 require scenarios such as binary system or peculiar glitching. However, such types of behaviour are already tightly constrained by the lack of an optical counterpart.

Are the unique characteristics of 1E 1207.4–5209 pointing towards a new class of NSs?
