**Abstract.** We present new medium-band uvby Strömgren and broad-band VI photometry for the central regions of the globular cluster  $\omega$  Cen. From this we have obtained differential reddening estimates relative to two other globulars (M 13 and NGC 288) using a metallicity-independent, reddening-free temperature index,  $[c] \equiv (u-v) - (v-b) - 0.2(b-y)$ , for hot horizontal-branch (HB) stars ( $T_e \ge 8,500$  K). We estimate color excesses of these hot HB stars using optical and near-infrared colors, and find clumpy extinction variations of almost a factor of two within the area of the cluster core. In particular, the greatest density of more highly reddened objects appears to be shifted along the right ascension axis by 1-1.5' when compared with less reddened ones. These findings complicate photometric efforts to investigate the star formation history of  $\omega$  Cen.

**Key words.** globular clusters: general — globular clusters: Omega Centauri

## 1. Introduction

Reddening uncertinties hardly affects the comparison between theory and observations, in particular for globular clusters affected by differential reddening. Current reddening estimates toward  $\omega$  Cen cluster around E(B-V)=0.11±0.02. However, the reddening map of Schlegel et al. (1998) indicates reddening variations of ~0.02 across the body of the cluster, while 2MASS data show a very clumpy reddening distribution outside 1° from the cluster center. In a recent investigation (Freyhammer et al. 2005), we presented *BRIJK* photometry for  $\omega$  Cen stars and we show that in or-

der to fit the anomalous giant branch ( $\omega$ 3) we need to adopt a 0.2 larger distance modulus, an increase of  $\sim$ 0.03 for the reddening, a metal-intermediate chemical composition and an age coeval with the bulk of the  $\omega$  Cen stars. This suggests that the  $\omega$ 3 branch could be a clump of stars located  $\sim$ 500 pc beyond the main body of  $\omega$  Cen , and that there may be a clumpy reddening distribution across the cluster. To further constrain the possibility of differential reddening toward  $\omega$  Cen , we use hot HB stars ( $T_e \geq 8,500$  K) and we adopt a reddening-free index based on Strömgren photometry, [c] =  $c_1 - 0.2(b - y)$ , where  $c_1 = (u - v) - (v - b)$

and E(b - y) = 0.74E(B - V), to estimate the reddening of individual HB stars.

## 2. Reddening estimates

A set of 110 uvby Strömgren images of  $\omega$  Cen were collected with the Danish Telescope, covering a field of 14'×14' on the cluster center. These have been supplemented with 30 uvby images of  $\omega$  Cen collected by Grundhal and 210 vby by Hilker with the same telescope (see Hilker & Richtler 2000). Photometry was performed with DAOPHOT/ALLFRAME and the merged star catalog includes  $\approx 2 \times 10^5$  stars. The typical photometric precision for faint HB stars is better than  $\sim 0^{\text{m}}03$  at  $y \approx 19.5$  and better than  $\sim 0.0^{\circ}$ 02 at  $u \approx 19$  mag. Our broad-band star catalog has been obtained from a set of UVI images collected with FORS1@VLT (Calamida et al. 2005, Freyhammer et al. 2005).

To obtain differential reddening estimates for  $\omega$  Cen we selected two GCs, M 13 ([Fe/H]=-1.54) and NGC 288 ([Fe/H]=-1.24), each marginally affected by reddening (E(B-V)=0.02, M 13; E(B-V)=0.03, NGC 288), and each possessing an extended blue HB for which both Strömgren and VI photometry exist. The comparison of  $\omega$  Cen , M 13, and NGC 288 hot HB stars in the u-y vs [c] and

V - I vs [c] planes shows that  $\omega$  Cen stars are systematically redder and display, at fixed [c], larger color dispersions (e.g.,  $\sigma_{u-y}$  = 0.085) compared to M 13 ( $\sigma_{u-y} = 0.037$ ) and NGC 288 ( $\sigma_{u-v} = 0.016$ ). The spread in color might be due to variations in the reddening toward  $\omega$  Cen since the [c] index is reddening free. In Calamida et al. (2005) we show that HB stars with  $T_e \ge 8,500$  are scarcely affected by metal abundance This means that only a reddening variation or a non stellar spectral energy distribution can move an object off the color-[c] relation. Supported by this evidence, we estimated the differential reddening for each hot HB star in  $\omega$  Cen by fitting fiducial sequences to the hot HB stars in M 13 and in NGC 288 in the (color)vs[c] planes, finding a mean reddening for  $\omega$  Cen of  $E(B-V)=0.11\pm0.03$ . Although the new mean reddening value agrees well with literature, reddening estimates for individual HB stars present a star-to-star scatter larger than our error budget. This suggests variable reddening toward the cluster core with a dispersion  $\sigma_{E(B-V)} \approx 0.04$  and supports the results of Cannon & Stobie (1973), who found reddening variations with  $\sigma_{E(B-V)} \approx 0.03$ -0.05. Finally, we investigated the spatial distribution of less-, more-, and average-reddened HB stars (selecting stars with color excess within  $\pm 1\sigma$ ). The distribution of these objects is clumpy: morereddened stars appear to be more concentrated in the N-W region of the cluster and their peak is shifted by 1-1.5' along the right ascension axis compared to the peaks of normal and lessreddened objects (see Fig. 1). Our results show that  $\omega$  Cen is indeed subject to variable reddening, which should be taken into account in photometric investigations. For a more detailed discussion see Calamida et al. (2005).
