Abstract. A sub-sampled deconvolution technique for crowded field photometry with the HST WFPC2 instrument was proposed by Butler (2000) and applied to search for optical counterparts to pulsars in globular clusters (Golden et al. 2001). Simulations showed that the method, which takes account of the point-spread function (PSF) spatial variation, can provide better star detection and recovers the resolution lost to aberrations and poor sampling. The original emphasis was on precision photometry in crowded fields. In the present work, we have extended this technique to determine proper motions of stars in globular clusters. Actual HST images of the globular clusters, along with realistic simulations of the globular clusters, were used to benchmark the technique for astrometric accuracy. The ultimate aim is to use this dynamical data to search for intermediate-mass black holes in globular cluster cores.

Key words. Proper motion—Deconvolution—Globular clusters—M71—NGC 6293—HST

1. Introduction

Accurate detection and centroiding of stars are important for measuring stellar proper motions, in the search for intermediate-mass black holes (IMBH) in globular cluster cores (Gebhardt et al. 2002; Anderson & van der Marel 2010). Observations and analysis of proper motions for many clusters are currently in progress (Lützgendorf et al. 2012). IMBH limits from HST proper motions have been presented for M15 (McNamara et al. 2003; van den Bosch et al. 2006), 47 Tuc (McLaughlin et al. 2006), and Omega Centauri (Anderson & van der Marel 2010). The high resolution and temporally consistent point spread function (PSF), over a suitably wide field, makes the

HST a natural choice for this work. However the PSF of the HST WFPC2 and to a lesser extent ACS WFC cameras are under-sampled and strongly spatially varying. This reduces the statistical accuracy of the fit and causes errors in star detection. To recover the resolution lost to aberrations and poor sampling, Butler (2000) developed the sub-sampled deconvolution technique for HST images.

2. Image deconvolution

2.1. Sub-sampled deconvolution technique

We have developed an iterative method to extract an accurate, spatially varying point spread function (PSF) to be used for Maximum Entropy Method (MEM) based deconvolution.

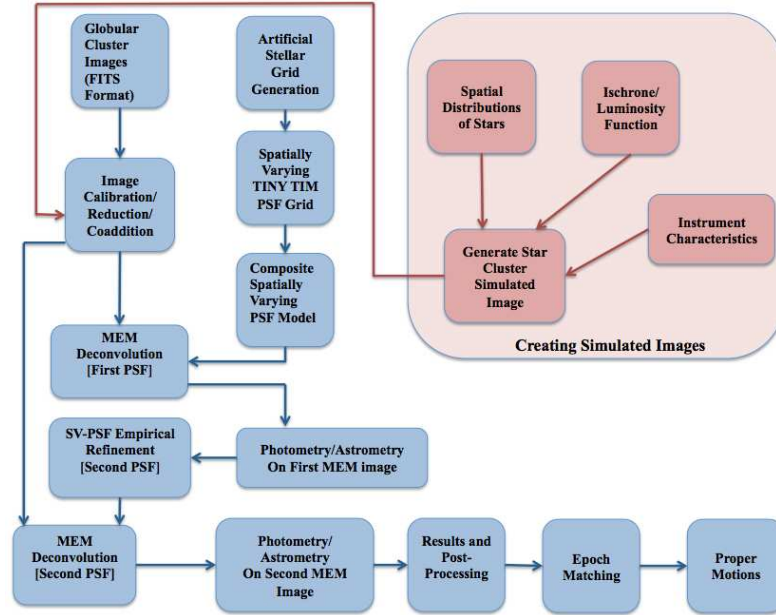

Fig. 1. Stellar proper motion in globular clusters. Sub-sampled deconvolution recovers resolution and results in better star detection. The photometric and astrometric accuracy of the technique is benchmarked using realistic simulated globular cluster images.

The flowchart in Fig. 1, outlines this sub-sampled deconvolution technique. An initial guess for the PSF is modeled from a sub-sampled spatially-varying TinyTim¹ PSF grid. Highly overlapping 256x256 pixel subimages of the science frame are deconvolved with the PSF appropriate for that position on the chip. The resulting deconvolved image is used for accurate star detection and first-pass photometry.

Empirical improvements over the Tiny Tim PSF have been achieved by generating a second subsampled, and quadratically spatially varying PSF, modelled from the cluster image itself. We use this in a second run through MEM.

Realistic simulations of WFPC2 cluster images, generated using Padova isochrones² and surface brightness profiles (Bertelli et al.

¹ Tool to model analytical HST PSFs. Refer to <http://www.stsci.edu/hst/observatory/focus/TinyTim> for more details.

2008), have been used to benchmark the photometric and astrometric accuracy of the technique.

2.2. Parallel sub-sampled deconvolution

Sub-sampled deconvolution can be easily broken down into components to be run in parallel. Using native multiprocessing in Python, we have written a parallelized version of the sub-sampled image deconvolution algorithm (Singh & Butler 2012) that can be executed on multicore machines. Another version, using Message Passing Interface (MPI)³ can be used on a cluster of machines. For benchmarking the computational speedup, we used a co-added HST WFPC2 PC1 chip image of the globular cluster NGC 6293, and a spatially varying analytical PSF model was generated from the Tiny Tim PSF grid. A large speedup was found

when a high fraction of code is running in parallel.

2.3. Star detection and photometry

Stars were detected, and measured by aperture photometry, on the deconvolved images as well as on the original, reduced and combined images. Depending on the degree of crowding, IRAF⁴ DAOFIND and SExtractor (Bertin & Arnouts 1996) were used. Star positions were corrected for the 34th row defect (Anderson et al. 1999) and the optical distortions (Anderson et al. 2003).

Fig. 2. NGC 6293 on the left and M71 on the right. The circles mark the stars with the largest motions between epochs. The clustering of such stars towards the corners of the NGC 6293 images indicates residual systematics in the distortion mapping.

2.4. Proper motion

Milli-arcsecond absolute proper motion is not possible with HST WFPC2 (McLaughlin et al. 2006). Relative stellar proper motions were determined by transforming star positions from each epoch to a reference-frame epoch. The IRAF task *geomap* was used to transform the coordinates using a second order polynomial solution, which takes care of the residual geometric distortions.

⁴ IRAF is distributed by the National Optical Astronomy Observatories, which are operated by the Association of Universities for Research in Astronomy, Inc., under cooperative agreement with the National Science Foundation.

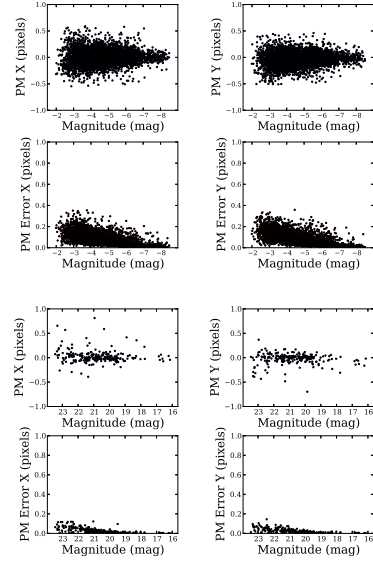

Fig. 3. NGC 6293 on the top and M71 on the bottom. X and Y proper motions in units of pixels (top) and error estimates (bottom). Errors are derived from the consistency of results obtained by processing several individual frames in each epoch, as per Anderson et al. (2006).

3. Results

We show preliminary results for 2 epochs of NGC 6293 and M71 in the F555W filter of the WFPC2 camera on the HST. Our results for M71 agree closely with Samra et al. (2012). The high velocity stars are marked for both the clusters in Fig. 2. Proper motion as a function of magnitude is shown in Fig. 3. A gaussian fit to the proper motion histogram is shown in Fig. 4. Velocity dispersion as a function of radial distance from the center of the cluster is shown in Fig. 5.

4. Conclusions

In these preliminary results, we found no signature of a central black hole in the globular clusters M71 and NGC 6293. We are now extending the proper motion study to deconvolved cluster images taken with the Advanced Camera for Surveys (ACS) camera on the HST. The spatially varying, sub-sampled deconvolu-

tion technique is also being adapted for adaptive optics images. Wide-field adaptive optics, with large telescopes, open a new frontier

in determining accurate parameters for most globular clusters that remain essentially unstudied because of high reddening, crowding, and large distances (Ortolani et al. 2011).
